

## Holocene Sedimentary Environmental Changes of Coastal Lowlands in Japan

UMITSU Masatomo

Department of Geography, Nagoya University

Chikusa, Nagoya 464-8601, JAPAN

### I. Introduction

There are a number of small coastal lowlands both on the Pacific and Sea of Japan coasts of the Japanese islands. Many studies have been carried out on both sea-level changes and landform evolution of the coastal lowlands including deltas in Japan. The stratigraphy and chronology of Holocene sediments of coastal lowlands relate to the sedimentary environment in which landforms have responded to sea-level changes in the past.

Typical Japanese riverine plains consist of alluvial fans, floodplains, and deltas from the inner to coastal regions in that order (Oya *et al.* 1988). However, considerable variation in landform is observed between the individual riverine coastal plains. There are plains without deltas, plains with broad flood plains, and plains in which alluvial fans occupy the entire plain. Large dunes or sandy barriers also develop along the shoreline of the Tsugaru, Akita, Shonai, and Niigata plains which located along the coast of the Sea of Japan. Rows of beach ridges are typically recognized in the Kuju-kuri plain, eastern Japan. Similar rows of beach ridges are also recognized in the Ishikari, Yufutsu, and Sendai plains in north and northeastern Japan. In general, relatively large plains

develop in regions where the land tended to subside during the late Quaternary.

## II. Holocene sea-level changes in Japan.

There are many opinions about the lowest sea-level during the last glacial maximum: -80 m (Oshima 1982, 1990); -95+-3m (Saito *et al.* 1989) ; -100 m (Fujii 1990); -127+-30 m (Oba 1988) ; -140 m (Iseki 1977) and so on. Many studies, however, regard the level around -100 m as the sea-level at that time (Ota and Omura 1991, etc.) . The extensions of paleoriver valleys formed during the last glacial maximum have been recognized in various places such as Tokyo and Osaka Bays and the continental shelves around the Japanese islands. The buried paleochannel under the bottoms of Tokyo and Osaka Bays are called the paleo-Tokyo River and paleo-Osaka River, respectively.

Sea-level changes during the late glacial period are still poorly understood. Sediments of the period in buried channels of riverine coastal lowlands are sandy and have a relatively high N-value (indicator of the hardness of sediments). Sea levels of the early Holocene reported in various sites are around -30 to -50 m (Ota *et al.* 1982, 1990). In the Kanto plain, an unconformity and the deposition of a conspicuous sandy bed are recognized between the contact of the Pleistocene and Holocene sediments in the riverine coastal plains. These sandy sediments were called as the Holocene basal gravel bed (HBG) by Endo *et al.* (1982), and they are considered to be sediments that were deposited in the period of Younger Dryas.

A slow rise of sea level in the early Holocene was reported by Matsushima (1987) and Endo *et al.* (1989) in the Kanto plain, eastern Japan. The period of slow transgression continued until approximately 8,500-8,300 yr BP. After that period, the sea level rose rapidly and reached a high stand in the middle Holocene around 7,000-6,000 yr BP. In many places, the sea level during that period is reported to have been 2-3 m higher than present level (Ota *et al.* 1982, 1990).

Minor fluctuations and temporal sea-level falls after the middle Holocene are reported on the Okhotsk coast (Maeda 1984, Sakaguchi *et al.* 1985, Hirai 1987), the Inland Sea coast (Naruse *et al.* 1984), the Chita Peninsula (Maeda *et al.* 1983), etc. In many places, minor sea-level falls are recognized around 4,500 and 3,000-2,000 yrs BP, and they are called middle Jomon small regression (Ota *et al.* 1982) and Yayoi regression (Ariake Bay Research Group 1965), respectively.

## III. Evolution of deltas and river-dominated riverine coastal plains in Japan.

Many studies on the sedimentary environments and landform evolution of riverine coastal plains have been done based on the examination of drilling logs and detailed fossil analysis of sediments. Detailed study on the basal topography of the Holocene and latest Pleistocene sediments in the Kanto plain was conducted by Endo *et al.* (1988). They also discussed the mode of deposition of the sediments including the courses of paleochannels in the plain.

Studies on the landform evolution and sediments of the riverine coastal plains of the Kanto plain

during the Holocene were done by Endo *et al.* (1982, 1987, 1989), Ando (1986, 1988), Ando *et al.* (1987, 1990), Matsushima (1987), Kosugi (1989), etc. Most of the studies involved reconstruction of the Holocene depositional environments of the riverine coastal plains, and determining the extent of marine transgression through diatom analysis. These studies clarified more detailed landform evolution and environmental change in comparison to previous studies. Based on diatom analysis (Kosugi 1985, 1986, 1988), Kosugi (1989) clarified the evolution of the Oku-Tokyo Bay which expanded to the north of the Tokyo lowland during the postglacial transgression. Evolution of the region was classified into three stages: (1) transgressive stage (10,000-6,500 yr BP); (2) maximum transgression (6,500-5,300 yr BP); and (3) regressive stage (5,300 yr BP-present). He also presented the Holocene relative sea-level curve and paleogeographical maps of the region at 9,500, 5,500 and 4,500 yr BP. Based on diatom and pollen analyses , Endo *et al.* (1987, 1989) discussed the landform evolution and vegetational change in a riverine coastal plain, and they pointed out that these physical environmental changes did not all occur independently of each other, but in part due to mutual interaction.

Further studies on the evolution of landforms and the deposition process of the Holocene sediments in riverine coastal plains with references to the postglacial transgression have been carried out in several riverine coastal plains. A study on the depositional sequence of the Nobi plain was done by Umitsu (1990). He classified the Holocene sedimentary sequence into the following stages: slow transgressive stage (10,000-8,500 yr BP); rapid transgressive stage (8,500-6,500 yr BP); aggradational stage (6,500-5,500 yr BP); and progradational stage (5,500 yr BP-present) which includes minor regressive stages during the periods of 5,000-4,500 yr BP and 3,000-2,000 yr BP (Fig. 2). Umitsu (1997) also discussed the regional differences of the sedimentary environment of delta front in the period around the Holocene / Pleistocene boundary (Fig. 3).

Studies on small estuarine coastal lowlands were also done by Ota *et al.* (1985, 1986), Matsubara *et al.* (1986), Fujimoto (1990, 1993), and Sawa *et al.* (1994) based on the analysis of molluscs and/or microfossils. They clarified the sedimentary environments, paleogeography, and sea-level changes of the region in the middle and late Holocene.

Ohira *et al.* (1994, 1996) discussed the evolution of peatland in small estuarine plains located along the shores of Lake Furen, northern Japan. They concluded that the formation and evolution of peatland is closely related to middle and late Holocene sea-level fluctuations.
